Python and Sage

To work through the Linear Algebra in this manual you need to be acquainted with how to run Sage. Sage uses the computer language Python so we'll start with that.

Python

Python is a popular computer language,[1] often used for scripting, that is appealing for its simple style and powerful libraries. The significance of 'scripting' is that Sage uses it in this way, as a glue to bring together separate parts.

Python is Free. If your operating system doesn't provide it then go to the home page www.python.org and follow the download and installation instructions. Also at that site is Python's excellent tutorial. That tutorial is thorough; here you will see only enough Python to get started. For a more comprehensive introduction see Python Team [2012b].

Comment. There is a new version, Python 3, with some differences. Here we stick to the older version because that is what Sage uses. The examples below were produced directly from Python and Sage when this manual was generated so they should be exactly what you see,[2] unless your version is quite different than mine. Here is my version of Python.

```
1  >>> import sys
2  >>> print sys.version
3  2.7.3 (default, Aug  1 2012, 05:16:07)
4  [GCC 4.6.3]
```

Basics Start Python, for instance by entering `python` at a command line. You'll get a couple of lines of information followed by three greater-than characters.

```
1  >>>
```

This is a prompt. It lets you experiment: if you type Python code and ⟨*Enter*⟩ then the system will read your code, evaluate it, and print the result. We will see below how to write and run whole programs but for now we will experiment. You can always leave the prompt with ⟨*Ctrl*⟩-*D*.

Try entering these expressions (double star is exponentiation).

```
1  >>> 2 - (-1)
2  3
3  >>> 1 + 2*3
4  7
5  >>> 2**3
6  8
```

---

[1]Written by a fan of Monty Python.   [2]Lines that are too long are split to fit.

Part of Python's appeal is that doing simple things tend to be easy. Here is how you print something to the screen.

```
>>> print 1, "plus", 2, "equals", 3
1 plus 2 equals 3
```

Often you can debug just by putting in commands to print things, and having a straightforward print operator helps with that.

As in any other computer language, variables give you a place to keep values. The first line below puts one in the place called i and the second line uses that.

```
>>> i = 1
>>> i + 1
2
```

In some programming languages you must declare the 'type' of a variable before you use it; for instance you would have to declare that i is an integer before you could set $i = 1$. In contrast, Python deduces the type of a variable based on what you do to it — above we assigned 1 to i so Python figured that it must be an integer. Further, we can change how we use the variable and Python will go along; here we change what is in x from an integer to a string.

```
>>> x = 1
>>> x
1
>>> x = 'a'
>>> x
'a'
```

Python lets you assign multiple values simultaneously.

```
>>> first_day, last_day = 0, 365
>>> first_day
0
>>> last_day
365
```

Python computes the right side, left to right, and those values are assigned to the variables on the left. We will often use this construct.

Python complains by *raising an exception* and giving an error message. For instance, we cannot combine a string and an integer.

```
>>> 'a'+1
Traceback (most recent call last):
File "<stdin>", line 1, in <module>
TypeError: cannot concatenate 'str' and 'int' objects
```

The error message's bottom line is the useful one.

Make a comment of the rest of the line with a hash mark #.

```
>>> t = 2.2
>>> d = (0.5) * 9.8 * (t**2)   # d in meters
>>> d
23.716000000000005
```

(Comments are more useful in a program than at the prompt.) Programmers often comment an entire line by starting that line with a hash.

As in the listing above, we can get real numbers and even complex numbers.[1]

```
1 >>> 5.774 * 3
2 17.322
3 >>> (3+2j) - (1-4j)
4 (2+6j)
```

As engineers do, Python uses j for the square root of -1, not i as is traditional in Mathematics.

The examples above show addition, subtraction, multiplication, and exponentiation. Division has an awkward point. Python was originally designed to have the division bar / mean real number division when at least one of the two numbers is real. However between two integers the division bar was taken to mean a quotient, as in "2 goes into 5 with quotient 2 and remainder 1."

```
1 >>> 5.2 / 2.0
2 2.6
3 >>> 5.2 / 2
4 2.6
5 >>> 5 / 2
6 2
```

Experience shows this was a mistake. One of the changes in Python 3 is that the quotient operation has become // while the single-slash operator is always real division. In the Python 2 we are using, you must make sure that at least one number in a division is real.

```
1 >>> x = 5
2 >>> y = 2
3 >>> (1.0*x) / y
4 2.5
```

Incidentally, the integer remainder operation (sometimes called 'modulus') uses a percent character: 5 % 2 returns 1.

Variables can also represent truth values; these are *Booleans*.

```
1 >>> yankees_stink = True
2 >>> yankees_stink
3 True
```

You need the initial capital: True or False, not true or false.

Above we saw a string consisting of text between single quotes. You can use either single quotes or double quotes, as long as you use the same at both ends of the string. Here x and y are double-quoted, which makes sense because they contain apostrophes.

```
1 >>> x = "I'm Popeye the sailor man"
2 >>> y = "I yam what I yam and that's all what I yam"
3 >>> x + ', ' + y
4 "I'm Popeye the sailor man, I yam what I yam and that's all what I yam"
```

The + operation concatenates strings. Inside a double-quoted string use slash-n \n to get a newline.

---

[1]Of course these aren't actually real numbers, instead they are floating point numbers, a system that models the reals and is built into your computer's hardware. In the prior example the distinction leaks through since its bottom line ends in 000000000005, marking where the computer's binary approximation does not perfectly match the real that you expect. Similarly Python's integers aren't the integers that you studied in grade school since there is a largest one (give Python the command import sys followed by sys.maxint). However, while the issue of representation is fascinating — see Python Team [2012a] and Goldberg [1991] — we shall ignore it and just call them integers and reals.

A string marked by three sets of quotes can contain line breaks.

```
 1  >>> a = """THE ROAD TO WISDOM
 2  ...
 3  ... The road to wisdom?
 4  ... -- Well, it's plain
 5  ... and simple to express:
 6  ... Err
 7  ... and err
 8  ... and err again
 9  ... but less
10  ... and less
11  ... and less. --Piet Hein"""
```

The three dots at the start of lines after the first is Python's read-eval-print prompt telling you that what you have typed is not complete. We'll see below that a common use for triple-quoted strings is as documentation.

A Python *dictionary* is a finite function. That is, it is a finite set of ordered pairs ⟨*key, value*⟩ subject to the restriction that no key can be used twice. Dictionaries are a simple database.

```
 1  >>> english_words = {'one': 1, 'two': 2, 'three': 3}
 2  >>> english_words['one']
 3  1
 4  >>> english_words['four'] = 4
 5  >>> english_words
 6  {'four': 4, 'three': 3, 'two': 2, 'one': 1}
```

Don't be mislead by this example, the words do not always just come in the reverse of the order in which you entered them. A dictionary's elements will be listed in no apparently-sensible order.

If you assign to an existing key then that will replace the previous value.

```
 1  >>> english_words['one'] = 5
 2  >>> english_words
 3  {'four': 4, 'three': 3, 'two': 2, 'one': 5}
```

Dictionaries are central to Python, in part because looking up values in a dictionary is very fast.

While dictionaries are unordered, a *list* is ordered.

```
 1  >>> a = ['alpha', 'beta', 'gamma']
 2  >>> b = []
 3  >>> c = ['delta']
 4  >>> a
 5  ['alpha', 'beta', 'gamma']
 6  >>> a+b+c
 7  ['alpha', 'beta', 'gamma', 'delta']
```

Get an element from a list by specifying its index, its place in the list, inside square brackets. Lists are *zero-offset* indexed, that is, the initial element of the list is numbered 0. Count from the back by using negative indices.

```
 1  >>> a[0]
 2  'alpha'
 3  >>> a[1]
 4  'beta'
 5  >>> a[-1]
 6  'gamma'
```

Specifying two indices separated by a colon gets a *slice* of the list.

```
1  >>> a[1:3]
2  ['beta', 'gamma']
3  >>> a[1:2]
4  ['beta']
```

You can add to a list.

```
1  >>> c.append('epsilon')
2  >>> c
3  ['delta', 'epsilon']
```

Lists can contain anything, including other lists.

```
1  >>> x = 4
2  >>> a = ['alpha', [True, x]]
3  >>> a
4  ['alpha', [True, 4]]
```

The function `range` returns a list of numbers.

```
1  >>> range(10)
2  [0, 1, 2, 3, 4, 5, 6, 7, 8, 9]
3  >>> range(1,10)
4  [1, 2, 3, 4, 5, 6, 7, 8, 9]
```

By default `range` starts at 0, which is good because lists are zero-indexed. Observe also that 9 is the highest number in the list given by `range(10)`. This makes `range(10)+range(10,20)` give the same list as `range(20)`.

A *tuple* is like a list in that it is ordered.

```
1  >>> a = ('fee', 'fie', 'foe', 'fum')
2  >>> a
3  ('fee', 'fie', 'foe', 'fum')
4  >>> a[0]
5  'fee'
```

However it is unlike a list in that a tuple is not *mutable* — it cannot change.

```
1  >>> a[0] = 'phooey'
2  Traceback (most recent call last):
3  File "<stdin>", line 1, in <module>
4  TypeError: 'tuple' object does not support item assignment
```

One reason this is useful is that because of it tuples can be keys in dictionaries while list cannot.

```
1  >>> a = ['Jim', 2138]
2  >>> b = ('Jim', 2138)
3  >>> d = {a: 'active'}
4  Traceback (most recent call last):
5  File "<stdin>", line 1, in <module>
6  TypeError: unhashable type: 'list'
7  >>> d = {b: 'active'}
8  >>> d
9  {('Jim', 2138): 'active'}
```

Python has a special value `None` for when there is no sensible value for a variable. For instance, if your program keeps track of a person's address and includes a variable `apartment` then `None` is the right value for that variable when the person does not live in an apartment.

Flow of control Python supports the traditional ways of affecting the order of statement execution, with a twist.

```
1  >>> x = 4
2  >>> if (x == 0):
3  ...     y = 1
4  ... else:
5  ...     y = 0
6  ...
7  >>> y
8  0
```

The twist is that while many languages use braces or some other syntax to mark a block of code, Python uses indentation. (Always indent with four spaces.) Here, Python executes the single-line block `y = 1` if x equals 0, otherwise Python sets y to 0.

Notice also that double equals `==` means "is equal to." In contrast, we have already seen that single equals is the assignment operation so that `x = 4` means "x is assigned the value 4."

Python has two variants on the above `if` statement. It could have only one branch

```
1  >>> x = 4
2  >>> y = 0
3  >>> if (x == 0):
4  ...     y = 1
5  ...
6  >>> y
7  0
```

or it could have more than two branches.

```
1  >>> x = 2
2  >>> if (x == 0):
3  ...     y = 1
4  ... elif (x == 1):
5  ...     y = 0
6  ... else:
7  ...     y = -1
8  ...
9  >>> y
10 -1
```

Computers excel at iteration, looping through the same steps.

```
1  >>> for i in range(5):
2  ...     print i, "squared is", i**2
3  ...
4  0 squared is 0
5  1 squared is 1
6  2 squared is 4
7  3 squared is 9
8  4 squared is 16
```

A `for` loop often involves a `range`.

```
>>> x = [4, 0, 3, 0]
>>> for i in range(len(x)):
...         if (x[i] == 0):
...             print "item",i,"is zero"
...         else:
...             print "item",i,"is nonzero"
...
item 0 is nonzero
item 1 is zero
item 2 is nonzero
item 3 is zero
```

An experienced Python person who was not trying just to illustrate `range` would instead write `for c in x:` since the `for` loop can iterate over any sequence, not just a sequence of integers.

A `for` loop is designed to execute a certain number of times. The natural way to write a loop that will run an uncertain number of times is `while`.

```
>>> n = 27
>>> i = 0
>>> while (n != 1):
...         if (n%2 == 0):
...             n = n / 2
...         else:
...             n = 3*n + 1
...         i = i + 1
...         print "i=", i
...
i= 1
i= 2
i= 3
```

(This listing is incomplete; it takes 111 steps to finish.)[1] Note that "not equal" is `!=`.

The `break` command gets you out of a loop right away.

```
>>> for i in range(10):
...         if (i == 3):
...             break
...         print "i is", i
...
i is 0
i is 1
i is 2
```

A common loop construct is to run through a list performing an action on each entry. Python has a shortcut, *list comprehension*.

```
>>> a = [2**i for i in range(4)]
>>> a
[1, 2, 4, 8]
>>> [i-1 for i in a]
[0, 1, 3, 7]
```

---

[1]The *Collatz conjecture* is that for any starting n this loop will terminate, but this is not known.

Functions   A *function* is a group of statements that executes when it is called, and can return values to the caller. Here is a naive version of the quadratic formula.

```
1  >>> def quad_formula(a, b, c):
2  ...        discriminant = (b**2 - 4*a*c)**(0.5)
3  ...        r1=(-1*b+discriminant) / (2.0*a)
4  ...        r2=(-1*b-discriminant) / (2.0*a)
5  ...        return (r1, r2)
6  ...
7  >>> quad_formula(1,0,-9)
8  (3.0,  -3.0)
9  >>> quad_formula(1,2,1)
10 (-1.0,  -1.0)
```

(One way that it is naive is that it doesn't handle complex roots gracefully.)

Functions organize code into blocks. These blocks of code may be run a number of different times, or may belong together conceptually. In a Python program most code is in functions.

At the end of the `def` line, in parentheses, are the function's *parameters*. These can take values passed in by the caller. Functions can have *optional parameters* that have a default value.

```
1  >>> def hello(name="Jim"):
2  ...        print "Hello,", name
3  ...
4  >>> hello("Fred")
5  Hello, Fred
6  >>> hello()
7  Hello, Jim
```

Sage uses this aspect of Python heavily.

Functions always return something; if a function never executes a `return` then it will return the value `None`. They can also contain multiple `return` statements.

Objects and modules   In Mathematics, the real numbers is a set associated with some operations such as addition and multiplication. Python is *object-oriented*, which means that we can similarly bundle together data and actions (in this context the functions are called *methods*).

```
1  >>> class DatabaseRecord(object):
2  ...        def __init__(self, name, age):
3  ...            self.name = name
4  ...            self.age = age
5  ...        def salutation(self):
6  ...            print "Dear", self.name
7  ...
8  >>> a = DatabaseRecord("Jim", 53)
9  >>> a.name
10 'Jim'
11 >>> a.age
12 53
13 >>> a.salutation()
14 Dear Jim
15 >>> b = DatabaseRecord("Fred",109)
16 >>> b.salutation()
17 Dear Fred
```

This creates two *instances* of the object `DatabaseRecord`. The `class` code describes what these consist of. The above example uses the *dot notation*: to get the age data for the instance `a` you write `a.age`. (The `self` variable can be puzzling. It is how a method refers to the instance it is part of. Suppose that at the prompt you type `a.name="James"`. Then you've used the name `a` to refer to the instance so you can make the change. In contrast, inside the `class` description code there isn't any fixed instance. The `self` gives you a way to, for example, get the `name` attribute of the current instance.)

You won't be writing your own classes here but you will be using ones from the libraries of code that others have written, including the code for Sage, so you must know how to use the classes of others. For instance, Python has a library, or *module*, for math.

```
1  >>> import math
2  >>> math.pi
3  3.141592653589793
4  >>> math.factorial(5)
5  120
6  >>> math.cos(math.pi)
7  -1.0
```

The `import` statement gets the module and makes its contents available.

Programs   The read-eval-print loop is great for small experiments but for more than four or five lines you want to put your work in a separate file and run it as a standalone program.

To write the code, use a text editor (one example is `Emacs`).[1] Use an editor with support for Python such as automatic indentation, and syntax highlighting, where the editor colors your code to make it easier to read.

Here is a first example of a Python program. Start your editor, open a file called `test.py`, and enter these lines. Note the triple-quoted documentation string at the top of the file; include such documentation in everything that you write.

```
1  # test.py
2  """test
3
4  A test program for Python.
5  """
6
7  import datetime
8
9  current = datetime.datetime.now()  # get a datetime object
10 print "the month number is", current.month
```

Run it through Python (for instance, from the command line run `python test.py`) and you should see output like `the month number is 9`.

Next is a small game. (It uses the Python function `raw_input` that prompts the user and then collects their response.).

```
1  # guessing_game.py
2  """guessing_game
3
4  A toy game for demonstration.
```

---

[1] It may come with your operating system or see http://www.gnu.org/software/emacs.

```
5   """
6   import random
7   CHOICE = random.randint(1,10)
8
9   def test_guess(guess):
10      """Decide if the guess is correct and print a message.
11      """
12      if (guess < CHOICE):
13          print "  Sorry, your guess is too low"
14          return False
15      elif (guess > CHOICE):
16          print "  Sorry, your guess is too high"
17          return False
18      print "  You are right!"
19      return True
20
21  flag = False
22  while (not flag):
23      guess = int(raw_input("Guess an integer between 1 and 10: "))
24      flag = test_guess(guess)
```

Here is the output resulting from running this game once at the command line.

```
1  $ python guessing_game.py
2  Guess an integer between 1 and 10: 5
3    Sorry, your guess is too low
4  Guess an integer between 1 and 10: 8
5    Sorry, your guess is too high
6  Guess an integer between 1 and 10: 6
7    Sorry, your guess is too low
8  Guess an integer between 1 and 10: 7
9    You are right!
```

As earlier, note the triple-quoted documentation strings both for the file as a whole and for the function. They provide information on how to use the guessing_game.py program as a whole, and how to use the function inside the program. Go to the directory containing guessing_game.py and start the Python read-eval-print loop. At the >>> prompt enter import guessing_game. You will play through a round of the game (there is a way to avoid this but it doesn't matter here). You are using guessing_game as a module. Type help("guessing_game"). You will see the documentation, including these lines.

```
1  DESCRIPTION
2      A toy game for demonstration.
3
4  FUNCTIONS
5      test_guess(guess)
6          Decide if the guess is correct and print a message.
```

Obviously, Python got this from the file's documentation strings. In Python, and also in Sage, good practice is to always include documentation that is accessible with the help command. All of Sage's built-in routines do this.

Sage

Learning what Sage can do is the goal of much of this book so this is only a very brief walk-through of preliminaries. See also [Sage Development Team, 2012] for a more broad-based introduction.

First, if your system does not already supply it then install Sage by following the directions at www.sagemath.org.

Command line Sage's command line is like Python's but adapted to mathematical work. First start Sage, for instance, enter sage into a command line window. You get some initial text and then a prompt (leave the prompt by typing exit and ⟨*Enter*⟩.)

```
1  sage:
```

Experiment with some expressions.

```
1  sage:  2**3
2  8
3  sage:  2^3
4  8
5  sage:  3*1  +  4*2
6  11
7  sage:  5  ==  3+3
8  False
9  sage:  sin(pi/3)
10  1/2*sqrt(3)
```

The second expression shows that Sage provides a convenient shortcut for exponentiation over Python's 2**3. The fourth expression shows that Sage sometimes returns exact results rather than an approximation. You can still get the approximation; here are three equivalent ways.

```
1  sage:  sin(pi/3).numerical_approx()
2  0.866025403784439
3  sage:  sin(pi/3).n()
4  0.866025403784439
5  sage:  n(sin(pi/3))
6  0.866025403784439
```

The function n() is an abbreviation for numerical_approx().

Script You can group Sage commands together in a file. This way you can test the commands, and also reuse them without having to retype.

Create a file with the extension .sage, such as sage_normal.sage. Enter this function and save the file.

```
1  def  normal_curve(upper_limit):
2      """Approximate  area  under  the  Normal  curve  from  0  to  upper_limit.
3      """
4      stdev  =  1.0
5      mu  =  0.0
6      area=numerical_integral((1/sqrt(2*pi)  *  e^(-0.5*(x)^2)),
7                              0,  upper_limit)
8      print  "area  is",  area[0]
```

Bring in the file with a load command.

```
1  sage:  load "sage_normal.sage"
2  sage:  normal_curve(1.0)
3  area  is  0.341344746069
```

Notebook Sage also offers a browser-based interface, where you can set up worksheets to run alone or with other people, where you can easily view plots integrated with the text, and many other nice features.

From the Sage prompt run `notebook()` and work through the tutorial.
